## HIGHLIGHTS

- Customized magnesium-doped wollastonite/nano-hydroxyapatite bioceramic scaffolds with precise porous structures were fabricated by 3D printing and coating technique.
- Composite bioceramic scaffold with 15 μm coating thickness exhibited the highest mechanical properties.
- Nano-hydroxyapatite coating can effectively inhibit the proliferation of human osteosarcoma cells.
- Composite bioceramic scaffold had significantly enhanced osteogenic induction on Rat bone marrow stem cells.

## ABSTRACT

It is still a major challenge to remove tumor cells and fill bone defects after tumor resection. Combined with the 3D printing technology, the composite bioceramics scaffolds were fabricated with intercon-nected porous magnesium-doped wollastonite (CSi-Mg) scaffolds as the architecture and nano-hydroxyapatite (n-HA) as the surface. The influence of manufacturing process on the n-HA layer thickness and degradation performance, biological performance and anti-tumor performance of the composite scaf-folds were investigated. The n-HA surface layer could effectively retard the degradation rate of CSi-Mg scaffolds and maintain high mechanical strength (over 90 MPa) after immersion in simulated body fluid for 3 weeks. Meanwhile, CSi-Mg/n-HA3 scaffold induced about 50 % of cell death for human osteosarcoma cells (MG-63) in vitro. CSi-Mg/n-HAx (x = 1, 3) scaffolds could improve the osteogenic performance of Rat BMSC. These findings demonstrate that the bioceramic composite scaffold with high strength, good osteogenic performance and anti-tumor performance is promising for the treatment of tissue injury after resection of osteosarcoma.

# 1. Introduction

Osteosarcoma is a common malignant tumor, mainly occurring in children and adolescents, The clinical presentation of osteosarcoma is not obvious, and there is no spontaneous fracture or severe pain in the early stage. As a result, the disease is not easy to diagnose, but tumors grow rapidly [1]. Osteosarcomas can cause large bone defects and limited movement, and can metastasise to the lungs [2]. At present, the treatment of osteosarcoma is mostly to remove the tumor site, and then supplemented by chemotherapy and other means [3]. However, excision usually results in a bone defect that exceeds the tissue's ability to heal itself [4], Moreover, it is difficult to completely eliminate tumor cells after resection and chemotherapy, and residual tumor cells may lead to local recurrence and surgical failure. Additionally, there is potential risk of bacterial infection during surgical procedure [5]. Based on this situation, a treatment method for bone defects after bone cancer surgery has been highly concerned and widely studied by researchers.

One of the most effective methods to treat bone defect is filling bone scaffold [6]. Bone regeneration is a complex process as molecular, biochemical, mechanical and cellular aspects have to be considered [7]. The ideal bone scaffold should not only have the appropriate mechanical properties, biological activity, degradability [8] and angiogenesis, but also have the function of killing tumor cells or inhibiting their growth. In the field of bone tissue repair, calcium silicate (CSi) bioceramics have attracted extensive attention due to their excellent bone conductivity, biological activity and degradability. The mechanical properties of calcium silicate ceramics can be effectively improved by doping magnesium into CSi during the synthesis process. Chemical co-precipitation method is a material manufacturing method that mixes different substances in solution, reacts to produce sediment, and forms the corresponding powder particles after drying the sediment. The material can be mixed evenly, and the chemical composition of the material is single. It has the advantages of simple process and good product performance, which is often used to prepare inorganic materials[9]. It has been pointed out that magnesium-doped wollastonite (CSi-Mg) bioceramic material has high mechanical properties and biological activity, and it has broad prospects for repairing bone defects [9–11]. In addition, additive manufacturing technology enables the creation of bone filled scaffolds with complex shapes, internal pores and controllable porosity [12–14]. The interconnected macropores are essential to supply sufficient space for cellular activity, nutrient transport and cell–cell interactions [15]. Extrusion 3D printing is an additive manufacturing method in which bioceramics inks made of organic binders and bioactive ceramics are stacked layer by layer to form a fixed 3D porous structure with interconnected pores. 3D-printed CSi-Mg scaffolds can promote the formation of new bone in the bone defects of rabbit mandible and skull [16–18]. The degradation of silicon and magnesium ions [17] is conducive to osteogenesis [19–21]. Although CSi-Mg scaffold has incomparable advantages compared with other bioactive materials, the slightly faster degradation rate, which mismatches with the bone tissue regeneration during the new bone ingrowth, restricts its application in the field of bone repair.

Hydroxyapatite (HA), which has the similar chemical composition as bone, is the most studied calcium phosphate ceramics [22]. HA has been shown to have good cell affinity and promote osteoblast adhesion and proliferation [23,24], but it has a low degradation rate [25]. In recent years, studies have also shown that nano-hydroxyapatite (n-HA) has anti-tumor effects [26–28]. And it can inhibit tumor growth, prevent tumor metastasis and improve sur-

vival rate of tumor-bearing rabbits [29]. These all reveal that the value of n-HA both as a bone-regenerating material and as an anti-tumor material. Therefore, we attempted to adsorb n-HA on the surface of CSi-Mg bioactive scaffolds to reduce degradation rate of CSi-Mg scaffolds and improve the mechanical properties, and the CSi-Mg/n-HA composite scaffolds with good anti-tumor property are also suitable for bone defects after bone cancer surgery.

In this study, the CSi-Mg powder was synthesized by chemical co-precipitation method and the CSi-Mg scaffold was fabricated by 3D printing technology, it was hypothesized that the n-HA surface layer can control the degradation rate of the CSi-Mg-based porous ceramics. The influence of manufacturing process parameters on the thickness of n-HA layer was studied, and the influence of the n-HA layer thickness on the degradation performance, mechanical properties and biological properties of the 3D printing CSi-Mg/n-HA composite scaffolds were analyzed, as well as the anti-tumor effect and osteogenesis performance of the composite scaffolds were explored.

# 2. Materials and methods

## 2.1. CSi-Mg and n-HA powders

The CSi-Mg powders with Mg doping (10 % Ca was substituted by Mg in CSi) were synthesized by a conventional chemical co-precipitation method as described in our previous work [9]. The as-calcined CSi-Mg powders were ground in a planetary ball miller (MP-2L; Chishun Sci&Tech Co., China) using 3.5 mm diameter zirconia ball media in ethanol for 6 h. The particle size distribution of the resulting CSi-Mg powders was below 10 μm. The n-HA powders were purchased from Shanghai Aladdin Bio-Chem Technology Co., ltd. The chemical composition of all materials was listed in the Supporting information, Table S1.

## 2.2. Preparation of CSi-Mg/n-HA composite scaffolds

For layer-by-layer printing of the CSi-Mg based scaffolds, the paste was prepared by mixing 5.8 g of powders with 4.0 g of 6 % polyvinyl alcohol (Sinopharm Chemical Reagent Co., ltd) solution. The paste was then added to a commercial syringe and extruded through a conical nozzle by the movement of a piston rod. A rectangular porous scaffold model with 3D architecture was designed using software. The moving speed of the dispensing unit was set to 6 mm/s, the nozzle diameter was 500 μm, the porosity was 55 %, and the layer thickness was 0.35 mm. Then, the scaffold samples were dried at 80℃ overnight to remove excess water in the pore struts, and followed by sintering in a micro-controller-controlled temperature furnace at a target temperature of 1140℃, in air atmosphere using similar heating schedules (heating rate was 2℃/min while maintaining at 320℃ and 500℃ for 45 and 60 min, respectively) and held at target temperature for 4 h, followed by cooling naturally (Table S2).

Sodium alginate (SA) (Sinopharm Chemical Reagent Co., ltd) solutions (1.0 %, 1.5 %, 2.0 % (w/v)) were prepared with distilled water, n-HA powders were added to sodium alginate solution and ethanol (Sinopharm Chemical Reagent Co., ltd), respectively, to obtain 4 % (w/w) n-HA/SA solution and n-HA/ethanol solutions (0.10 g/ml, 0.15 g/ml, and 0.20 g/ml). The CSi-Mg scaffolds were first dipped in n-HA/ethanol solution under vacuum for 2 min and stirred in air for target time (5 min, 10 min, or 15 min), followed by drying for 15 min. Next, the scaffolds were immersed in n-HA/SA solution under vacuum until no bubbles emerged from the scaffolds (10 min) followed by drying (70℃, 15 min). These scaffolds prepared in n-HA/ethanol solution and n-HA/SA solution

for 1, 2, 3 times were respectively named as CSi-Mg/n-HA1, CSi-Mg/n-HA2, CSi-Mg/n-HA3.

## 2.3. Physicochemical characterization of the powders and scaffolds

The phase composition of the CSi-Mg and *n*-HA powders was verified by X-ray diffractometer (XRD; Rigaku Co., Japan) at 40 kV/40 mA. Data were collected between 20° and 60° with a step of 0.02°/2θ and a dwell time of 1.5 s to identify any crystalline phase of the powders. The inorganic ion content in CSi-Mg powder was measured by inductively coupled plasma-optical emission spectrometry (ICP-OES; Thermo Icap 6000 series). The powders were observed by using the scanning electron microscopy (SEM, S-4800; Japan) at 10 kV. The particle size distribution was analyzed by dynamic light scattering (DLS, Malven Instrument 2000) in purified water medium.

## 2.4. Mechanical test of scaffolds

The compressive strength and elastic modulus of the bioceramic scaffolds ($7 \times 7 \times 7$ mm) were tested the direction parallel to the pore orientation (along the vertical Z direction) on a universal testing machine (Instron 5566, Germany) at a cross-head speed of 0.5 mm/min. Six samples were used for replicates of this experiment. The test was carried out by the procedure described in ASTM C773-88. The elastic modulus was determined from the linear region of the stress versus strain response.

## 2.5. Degradation and mechanical stability evaluation in vitro

In order to evaluate the weight loss (degradation) of the scaffolds ($7 \times 7 \times 7$ mm), the scaffolds (W0) were respectively immersed in simulated body fluid (SBF) with an initial pH 7.40 at 37℃ with a liquid/solid ratio of 200 mL/g. After immersing for every 48 h, the pH of solutions was measured. The samples were rinsed with ethanol and then dried up to mass constancy (Wt) before weighing. The weight decrease was expressed as the following equation: weight loss = Wt/ W0 $\times$ 100 %. The compressive strength of the as-dried scaffolds was also determined by Instron testing machine.

## 2.6. Assessment of bioactivity in SBF

The scaffolds were immersed in SBF at 37℃, the formation of HA and the degradation of SA were monitored on the surface of samples for different time stages. After soaking for 1 week to 4 weeks, the scaffolds were washed with ethanol and observed using SEM. Prior to examination, the samples were coated with a thin layer of gold.

## 2.7. Cell culture in vitro

MG63 cells were provided by Procell (China). The MG63 cells were cultivated in Dulbecco's modified Eagle medium high-glucose (DMEM) (KeyGEN BioTECH, China), which included 10 % fetal calf serum (Procell, China), 100 U/mL penicillin and 100 mg/mL streptomycin (Procell, China), at a 37℃ incubator with 5 % $CO_2$.

Rat bone-marrow stem cells (Rat BMSC) were provided by Procell (China). The Rat BMSC were cultivated in Dulbecco's modified Eagle medium low-glucose (DMEM) (KeyGEN BioTECH, China), which included 10 % fetal calf serum (Procell, China), 100 U/mL penicillin and 100 mg/mL streptomycin (Procell, China), at a 37℃ incubator with 5 % $CO_2$ [30].

The extracts of scaffolds were prepared in advance for research in vitro. The preparation process of the extracts was briefly described as follows: prepare the CSi-Mg, CSi-Mg/n-HA1, CSi-Mg/

n-HA3 (diameter of 10 mm, thickness of 1 mm). Then these four scaffolds were soaked into 1 mL serum-free medium, and incubated on the shaker at 37 °C for 24 h respectively. The medium was then extracted and sterilized with a 0.22 μm Millipore filter.

### 2.7.1. Apoptosis was detected by Annexin V-EGFP PI double staining

Monolayer adherent cells at logarithmic growth stage were digested with 0.25 % trypsin and blown into single cells. The cells were inoculated into 6-well plates at a density of $10 \times 10^4$ / dish and cultured in a 5 % $CO_2$ incubator at 37℃ [31]. After the cells were attached to the wall, they were divided into experimental groups for experimental treatment. After 7 days of culture, cells were collected, stained with Annexin V-EGFP Apoptosis Detecyion kit (KeyGEN BioTECH China) and detected by BECKMAN COULTER CytoFLEX flow cytometer.

### 2.7.2. Cell viability staining

The cells were inoculated onto the scaffolds in an incubator of 37℃ and 5 % carbon dioxide. After 3 and 7 days of culture, the culture medium was sipped and washed with PBS for 3 times. According to the manufacturer's instructions, the living and dead cells were detected by calcein /PI cell viability/cytotoxicity assay kit (Beyotime, Cat: C2015M, Shanghai, China). The cells were then observed under a laser scanning confocal microscope (Olympus, Japan). Cell survival was calculated by mean fluorescence intensity.

### 2.7.3. Caspase-3 colorimetric assay

Human bone cancer cell MG63 was divided into four groups (control, CSi-Mg, CSi-Mg/n-HA1, CSi-Mg/n-HA3). All the MG63 cells were digested by trypsin, then the digested cells were centrifuged (4℃, 2000 rpm, 5 min) and resuspended in 150 μL of a lysis buffer and 1.5 μL DTT from a caspase-3 (KGA202, KeyGEN, China), placed on ice for 1 h, and vortexed four times for 10 s each time. The cell suspension was centrifuged (10,000 rpm, 1 min), and the supernatant was transferred to a 1.5-mL centrifuge tube, which was then placed on ice. Approximately 50 μL of a $2 \times$ reaction buffer and 5 μL of the caspase-3 substrate were added to each 50-μL sample, incubated at 37℃ in the dark for 4 h, and then analyzed by using a microplate reader at a wavelength of 405 nm [32].

### 2.7.4. Wound-healing assay

In the cell scratch experiment, MG63 cells were cultured in 6-well plates (Corning, USA) and incubated until reaching 80 to 90 % confluence. The lines were gently crossed vertically with the head of a 200 ul spear to ensure that there were no cells at the lines. PBS was used for 3 times to wash away the lines. The serum-free medium extract containing each grouping material prepared in advance was added to the well plate. At 0 h and 24 h, cell scratch pictures were taken under microscope (Nikon, Japan), and the cell migration of each group was analyzed by Image J (Ver 1.53q) software.

### 2.7.5. Colony formation assay

The cells were digested to make a suspension and counted; 1,000 cells were seeded in each well of a 6-well plate. The medium was changed every 3 days. After 10 days, the cells were fixed with 4 % paraformaldehyde for 15 min, then stained with crystal violet solution for 30 min and photographed with a digital camera, and the clone formation rate was calculated.

### 2.7.6. Transwell migration asssy

In Transwell chamber (pore size 8 μm; Costar, NY, USA), $2 \times 10^4$ cells were cultured with 200 μL serum-free medium in the upper chamber, and 700 μL medium plate containing 10 % FBS in the lower chamber. The cells were cultured at 37 °C and 5 % $CO_2$ for 24 h. The cells were fixed with 500 μL 4 % paraformaldehyde at

room temperature for 20 min, then stained with 500 μL crystal violet solution for 30 min. The cells in the upper chamber were wiped and the chamber was cleaned with deionized water and then photographed with a microscope (Olympus, Japan).

### 2.7.7. RNA extraction and qRT-PCR

Total cellular RNA was extracted by TRIzol reagent and centrifugal column method (TransGen, China). RNA concentration and mass were measured by NanoDrop spectrophotometer (ND-100, Thermo Fisher Scientific). QRT-PCR was performed and the mRNA expression levels were normalized to GAPDH (Thermo Fisher Q5 ABIQuantStudio 5 U.S.). Each sample was determined three times. Relative gene expression was determined by $2^{-\Delta\Delta CT}$. The forward and reverse primer sequences utilized are listed in Table S3.

### 2.7.8. Cell morphology staining

100,000 cells were inoculated onto the scaffold and incubated for 24 h. The scaffold was transferred to a new culture plate. Part of the scaffold was removed on the third day and the seventh day of culture. 0.5 % TritonX-100 was permeated for 5 min, then atrin-tr Acker Green was incubated with the cells at room temperature for 30 min. Finally, cells were stained with DAPI. Laser scanning confocal microscope (Olympus, Japan) 4 × is used for photography.

### 2.7.9. CCK-8 assay

The cells were digested into single cell suspension and counted to $2 \times 10^4$/mL. 100 μL cells were spread in 96-well plates peer well. Each sample was set with 6 multiple holes, and 100 μL PBS was added into the edge holes. 10 μL CCK-8 (Shanghai yuanye Bio-Technology, China) was added to each well on the 1st, 3rd, 5th and 7th day, and incubated for 2 h. The OD value of CCK-8 was 450 nm by microplate reader (MOLECULAR DEVICES).

### 2.7.10. Alizarin-red s assay

Briefly, Rat BMSC were plated into a 24-well plate and cultured in osteogenic inductive media with different scaffolds extracts (CSi-Mg, CSi-Mg/n-HA1, CSi-Mg/n-HA3). After 14 days, cells were fixed with 4 % (v/v) paraformaldehyde and stained with alizarin red S (Servicebio) (2 %) at pH 4.2 for 20 min and then washed with deionized water. The samples were air-dried, and photos were taken under a light microscope.

### 2.8. Statistical analysis

All the data above were expressed as the mean value ± standard deviation (SD) and analyzed with the one-way analysis of variance (ANOVA). In all cases the results were considered statistically significant at a p-value < 0.05.

## 3. Results and discussion

### 3.1. Primary characterization of the powders and scaffolds

Fig. 1 shows the brief illustration of the study. The architecture of the scaffolds was fabricated by the 3D printing technique and nano-HA surface layer was obtained via immersion method. The liquid bridge in n-HA/ethanol makes n-HA particles adhere to the surface of the support [33]. After the support is removed and dried, solid bridge is formed between particles and particles as well as between particles and the support, making n-HA particles adsorb on the surface of the support [34,35]. SA solution not only protects the n-HA adsorbed on the surface of the scaffold, but also serves as the base surface for the next layer of n-HA adsorbed. Finally, the composite scaffolds were fabricated with interconnected porous CSi-Mg scaffolds as the architecture and n-HA as the surface.

XRD pattern of the n-HA particles confirmed that n-HA exhibited a typical phase composition of HA (PDF#09–0432). The spectral data confirmed that the CSi-Mg sample has high crystallinity, which coincides with the wollastonite-2 M (β-CSi; PDF# 27–0088), indicating pure wollastonite nature (Fig. 2A). According to the SEM observation, the particle size of CSi-Mg powders after calcination are all<10 μm (Fig. 2B) and the particle size of n-HA powders are<100 nm (Fig. 2C). Also, it is worth noting that the measured Mg content in CSi-Mg powder was 2.10 wt%, which was close to the theoretical data (2.12 wt%) calculated by the 10 % Ca substitution by Mg in the stoichiometric wollastonite.

The fracture surface of the scaffolds without and with n-HA are shown in Fig. 2D and 2E. The horizontal side pores with rectangular morphology could be observed and the surface of the scaffold is covered with n-HA layer. Fig. 2F and 2G show the influence of different immersion time (5 min-15 min) in n-HA/ethanol solution and different SA concentration (1.0 %-2.0 %) on the thickness of n-HA layer. The thickness of n-HA layer gradually increases with increasing soaking time. However, the thickness increases slowly with the increase of immersion time from 10 min to 15 min. When immersion in 1.5 % SA solution, the composite scaffolds showed thicker n-HA layer (∼16 μm) than those immersion in a lower (1.0 %) or higher (2.0 %) concentration. This is because the flow performance of 1.0 % SA solution is too good to take away the n-HA of the scaffold surface. When the concentration exceeds 2.0 %, the SA solution will be difficult to enter the pores of the scaffolds. Finally, we choose immersion time for 10 min, SA concentration for 1.5 % to continue next experiment.

The thickness of n-HA layers with varying n-HA/ethanol solution concentration (0.1 g/ml-0.2 g/ml) and coating number (1–3) is shown Fig. 2H and 2I. The thickness of the n-HA layer increased with increasing n-HA/ethanol solution concentration and it also increased with increasing coating number. When solution concentration at 0.2 g/ml, the n-HA layer of CSi-Mg/n-HA1 was evenly distributed on the surface of the CSi-Mg scaffold. With the increase of coating number from 1 to 3, the thickness of the n-HA layers was not uniform. Even when the coating number exceeds 3 times, the pore of scaffold will be blocked. Both the CSi-Mg/n-HAx (x = 1, 2, 3) composite scaffolds with solution concentration at 0.1 g/ml and 0.15 g/ml had uniform surface n-HA layers, and the CSi-Mg/ n-HA composite scaffold with solution concentration at 0.15 g/ml had suitable n-HA layer thickness. These investigations suggest that the solution concentration and coating number are important factors to influence n-HA layer thickness of the composite scaffold. Finally, we choose n-HA/ethanol solution (0.15 g/ml) and CSi-Mg/ n-HA1 (5 μm) and CSi-Mg/n-HA3 (15 μm) to continue next experiment.

### 3.2. Degradation behavior of the scaffolds in vitro

To further understand the effect of surface coating on mechanical strength attenuation of the scaffolds, especially the effect of coating thickness on strength, the CSi-Mg/n-HAx scaffolds were kept in SBF up to 3 weeks (Fig. 3A). Fig. 3B shows the change of pH value in SBF with the increase of soaking time. It is seen that the pH value in SBF gradually increased when immersing the CSi-Mg scaffolds, which may be related to the binding effect between $SiO_4^{4-}$ released during the degradation of scaffolds and H+ in solution [11]. In the solution of CSi-Mg/n-HA1 and CSi-Mg/ n-HA3, the pH value decreased and then increased. Scaffolds surface with adsorption by sodium alginate, dissolved in solution, $Ca^{2+}$ in solution combined with sodium alginate formation water gel [36]. H+ as cationic complement the loss of $Ca^{2+}$ in the solution, cause a drop in pH value. The pH value of the CSi-Mg/n-HA3 solu-
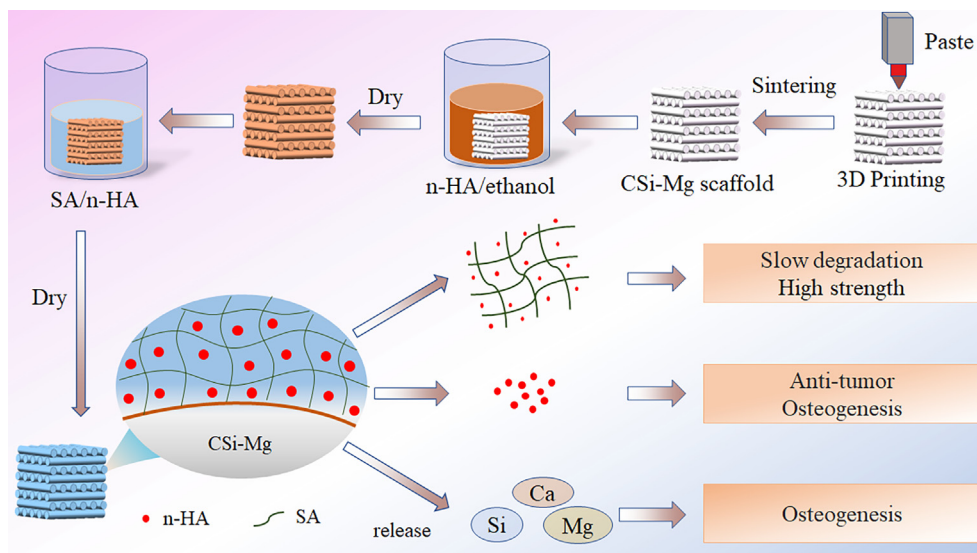

**Fig. 1.** The brief illustration of the study.

tion is higher because the CSi-Mg/n-HA3 scaffold has more *n*-HA particles. High *n*-HA proportion exhibit high concentration of hydroxide (OH) ion cause a rise in pH value [37]. The pH value of the solution gradually increased under the influence of the degradation of the scaffold and *n*-HA. It could be seen that the solution was flat and weak alkaline at 21 days, which is favorable for osteogenic cell growth in the porous scaffolds.

Fig. 3C shows the change in weight as a function of immersion time. The weight of all CSi-Mg/*n*-HAx scaffolds reduced within the initial 1 week, but the pure CSi-Mg scaffolds had the highest weight loss rate (Fig. 3D). From the weight change of the scaffolds in Fig. 3C, the weight loss of the CSi-Mg/*n*-HAx (x = 1, 3) scaffolds is mainly caused by the *n*-HA falling from the scaffolds surface. This shows that the *n*-HA layer can stop the CSi-Mg scaffolds from degrading. The *n*-HA particles on the surface of the CSi-Mg/n-HA1 scaffold is less than that of CSi-Mg/n-HA3, so its weight loss rate is lower due to the stronger coating effect. After soaking for 2 weeks, the weight loss of the CSi-Mg/n-HA3 scaffolds was the largest, which was due to the *n*-HA dropped or degraded on the surface of the scaffolds. The *n*-HA layer dropped and degradation on the CSi-Mg/n-HA1 scaffold in the second week were also the main factors of the weight loss. The weight loss rate of all CSi-Mg/*n*-HAx scaffolds tended to be gentle after 3 weeks. Although the weight loss rate of the CSi-Mg/n-HA3 scaffold was 7.3 % after 3 weeks, its weight value was still bigger than the other two scaffolds.

As for the strength decay during this process, the compressive strength of CSi-Mg scaffolds decreased by nearly 20 % within 3 weeks, from ∼ 91 MPa to ∼ 73 MPa. The CSi-Mg/*n*-HAx (x = 1, 3) scaffolds changed slowly with appreciable compressive strength (81–91 MPa) after the whole immersion stage of 3 weeks (Fig. 3E). Overall, all the composite scaffolds showed the same trend that compressive strength decreased continuously as a function of time. The CSi-Mg/n-HA3 scaffolds showed the largest compressive strength (91 MPa) in 3 weeks. The change trend of elastic modulus is consistent with that of compressive strength (Fig. 3F). The *n*-HA layer reduced the porosity of the scaffolds and improved mechanical properties correspondingly. This can also be confirmed by the representative stress–strain curves for the samples during compression test (Fig. 3G). In addition, the SA in the *n*-HA layer dissolved in solution to form hydrogels, which will fill tiny gaps on the surface of the scaffold to improve its mechanical properties. It implies that the surface adsorption of *n*-HA and SA contributed

to the higher mechanical endurance of the scaffolds. It is reasonable to conclude that, the CSi-Mg/*n*-HAx composite scaffolds show a good mechanical stability in aqueous medium with physiological pH condition, which would be adapt for the large segmental bone defect applications.

### 3.3. Surface reactivity of scaffolds

To further determine the suitability of the CSi-Mg/*n*-HAx scaffolds for application in bone repair, their surface reactivity was tested by immersing SBF for 0–3 weeks (Fig. 4). The spherical particles are deposited on the surface of the CSi-Mg scaffold within 1 week. After 3 weeks, the surface of the scaffolds was covered with a layer of HA mineral. The formation of biomimetic HA is responsible for the strong bonding between implants and host bone tissue. However, there was no HA mineral on the surface of the CSi-Mg/n-HA1 scaffold until the third week, probably because the SA on the surface of the scaffold formed hydrogel with $Ca^{2+}$ in the solution [36]. The reduction of $Ca^{2+}$ affects the formation of HA mineral. There was also no HA mineral on the surface of the CSi-Mg/n-HA3 scaffolds within 3 weeks and the CSi-Mg/n-HA3 scaffold needed more time to form the mineral layer.

### 3.4. anti-tumor effect in vitro

SEM was used to observe the morphology and attachment of human osteosarcoma MG63 cells cultured on three kinds of scaffolds for three days. We found that cells spread well on the CSi-Mg scaffolds (Fig. 5A) and had good cellular state (Fig. 5D). It was seen that MG63 cells did not well attach on the surface of the CSi-Mg/n-HA1 scaffolds (Fig. 5B). On the contrary, the cells slightly curled (Fig. 5E) and did not spread well. In addition, the MG63 cells did not attach well on the surface of the CSi-Mg/n-HA3 scaffolds (Fig. 5F) and spread further reduce (Fig. 5C). These results shows that the *n*-HA layer could inhibit the growth of human bone MG63 tumor cells [38–40].

The apoptotic rates of the MG63 cells treated with different scaffolds extract for 7 days were quantified (Fig. 6A, B). CSi-Mg/*n*-HA scaffolds increased the apoptotic rate of the cells in a dose-dependent manner. With the coating time rising from 1 to 3, the percentage of early and late apoptotic cells increased from 4.46, 12.98 % to 6.45, 29.15 %. This suggests that the coating on the scaf-

folds can effectively promote cell apoptosis [41]. The scanning microscopy images in Fig. 6C indicated different cells in cell viability staining experiment (red fluorescence was used to dye the died cells, green fluorescence was used to dye live cells). In CSi-Mg/*n*-HA1 and CSi-Mg/*n*-HA3 groups, strong red fluorescence of 7 days

indicates a high number of death cells. The survival rate (Fig. 6D) indicates that CSi-Mg/n-HA1 and CSi-Mg/n-HA3 scaffolds are able to promote cell death. By day 7, CSi-Mg/n-HA3 scaffold induced about 50 % of cell death for human osteosarcoma cells (MG-63) in vitro. In the cell morphology staining diagram (Fig. 6E), blue flu-
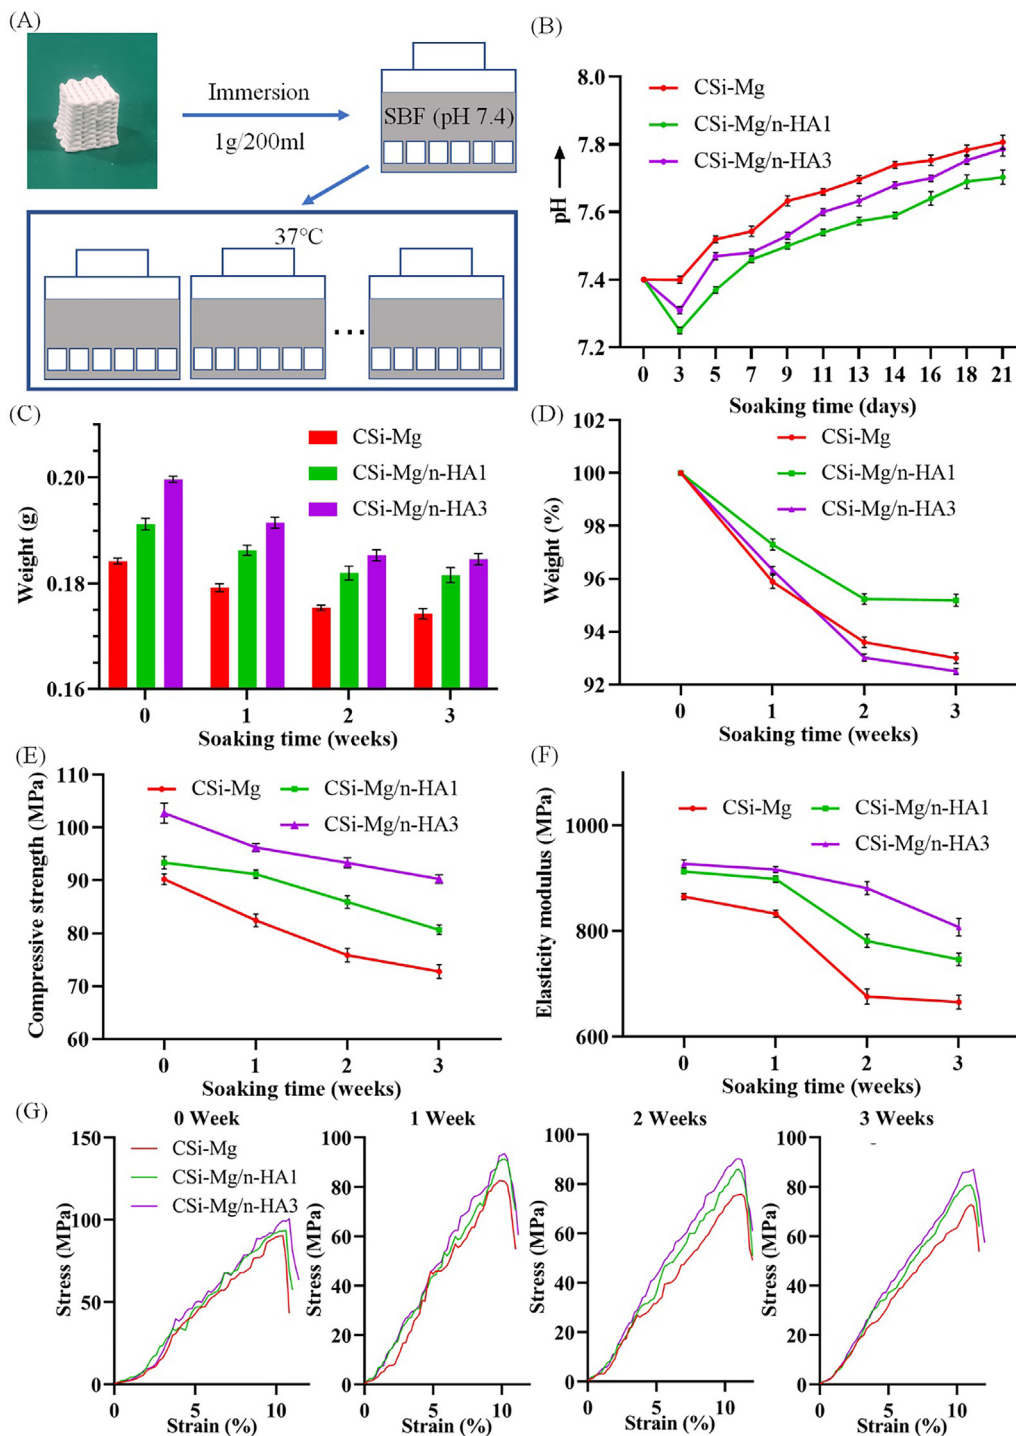

**Fig. 3.** Degradation test in SBF (pH 7.4) for 3 weeks. (A) Schematic illustration of the scaffolds soaking in SBF. (B) pH changes in SBF. (C) Changes in weight of the scaffolds as a function of soaking time. (D) Changes in weight (%) of the scaffolds as a function of soaking time. The elastic modulus in (F) was calculated from the slope of the linear segment of (G) the stress strain curve.

orescence was used to dye the DAPI and green fluorescence was used to dye ACTIN. The fluorescence intensity shows CSi-Mg group exists more cells. This indicates that CSi-Mg/n-HA1 and CSi-Mg/n-HA3 scaffolds are able to inhibit cell proliferation. In Fig. 6F, we performed a colony formation assay using the extracts of scaffolds (the cells in the plate were stained blue), and compared with the control group, fewer clones were formed in the CSi-Mg/n-HA1 and CSi-Mg/n-HA3 groups. Number of clone formation shows it clearly (Fig. 6G). On the other hand, CCK-8 assay (Fig. 6H) also

showed that CSi-Mg/*n*-HAx (x = 1, 3) scaffolds could inhibit the proliferation of tumor cells.

Transwell migration assay (Fig. 7A) showed that the minimum number of tumor cells migrated through the chamber after treatment with the CSi-Mg/n-HA1 scaffolds extract and the CSi-Mg/n-HA3 scaffolds extract (Fig. 7B). Wound-healing assay (Fig. 7C) showed tumor cells co-cultured with the CSi-Mg/n-HA3 scaffolds extract (Fig. 7C c5, c6) significantly delayed wound closure compared to the CSi-Mg scaffolds extract medium (Fig. 7C c1, c2) or
**Fig. 4.** SEM images of the surface of scaffolds after soaking in SBF for 1–3 weeks.

**Fig. 5.** SEM images of MG63 cultured in three kinds of scaffolds for three days. (A, D) CSi-Mg scaffolds. (B, E) CSi-Mg/n-HA1 scaffolds. (C, F) CSi-Mg/n-HA3 scaffolds.

CSi-Mg/n-HA1 (Fig. 7C c3, c4) scaffolds extract medium. The area of wound healing (Fig. 7D) suggested that the coated scaffolds can decrease the migration of tumor cells [42]. In RNA extraction and qRT-PCR, our results demonstrated that gene expression of Ki-67

(Fig. 7E) decreased indicating a less cell proliferative activity and more induced apoptosis [43]. It was found that Bcl-2 gene was inhibited in the experimental group compared with the control group (Fig. 7E), The expression of Bcl-2 gene can inhibit cell apop-
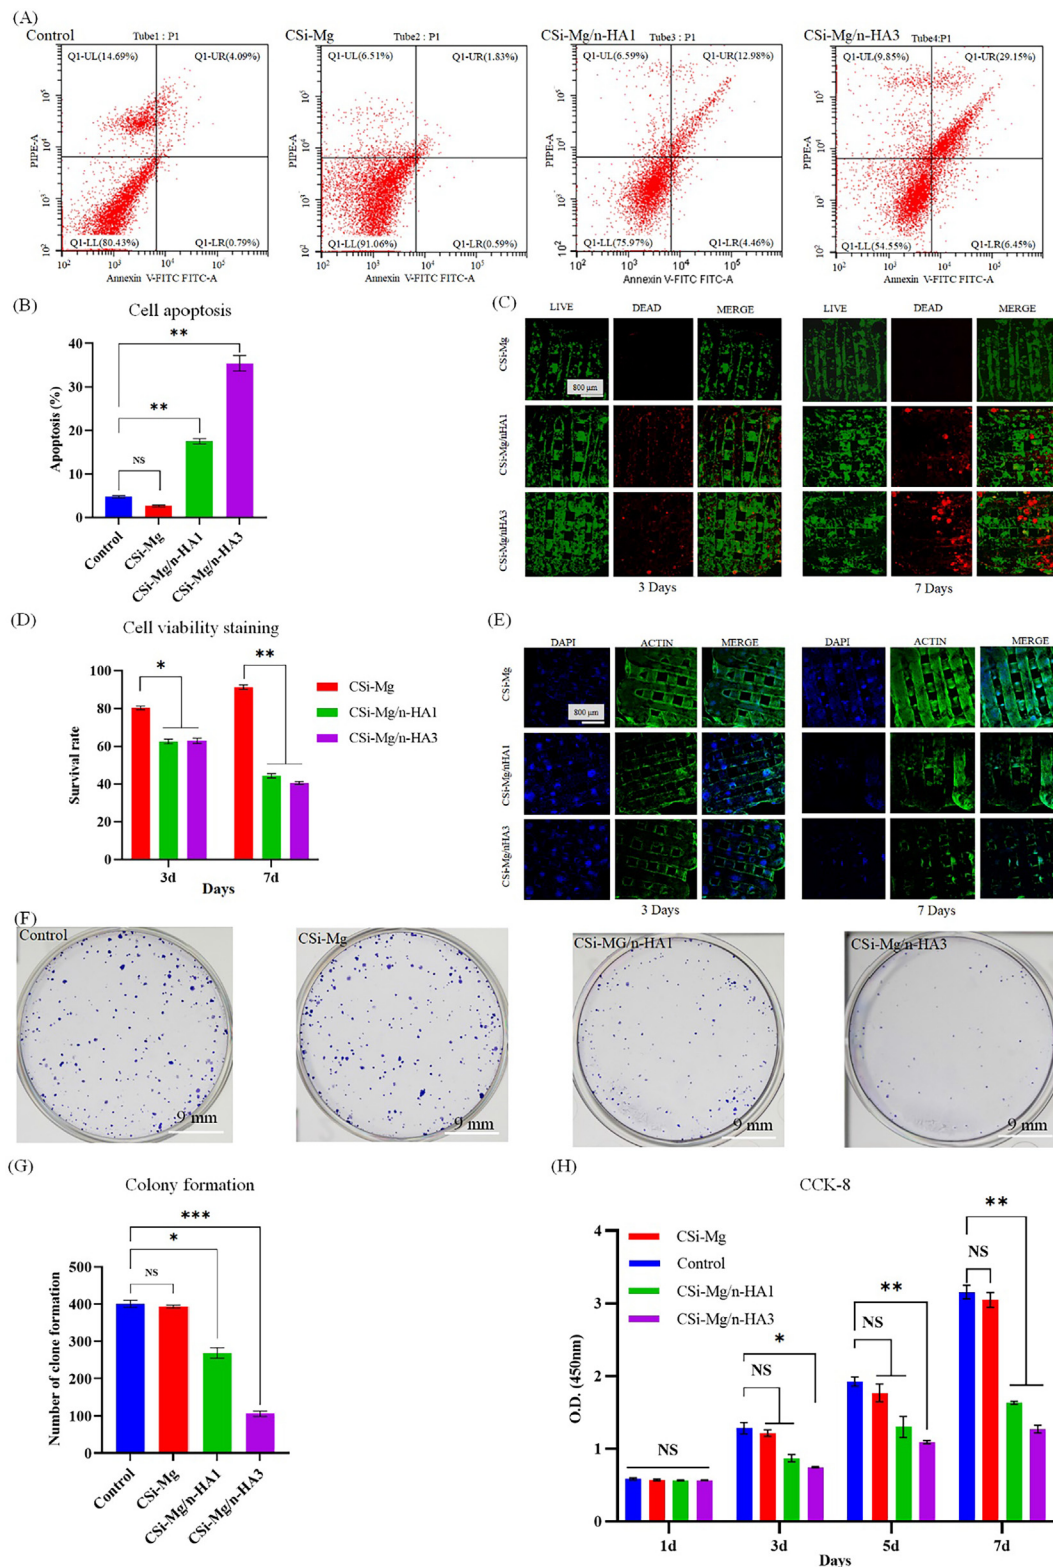

**Fig. 6.** Scaffolds can inhibit the proliferation of tumor cells in vitro. tosis [44]. The expression of Bcl-2 gene in the experimental group was decreased, indicating that the experimental group promoted cell apoptosis. The activity of caspase-3 was detected by spectrophotometry (Fig. 7F), and the CSi-Mg/n-HA1 and CSi-Mg/n-HA3 groups were significantly higher than the control group. This

indicates that the activation of caspase-3 promoted cell apoptosis [32].

The mechanism of *n*-HA induced tumor cells apoptosis has been extensively investigated but is still debating, studies have shown that particles<5 μm could induce more obvious cytotoxicity [26–

**Fig. 7.** Scaffolds can reduce cell migration in vitro. (A) Transwell experiment and (B) migration cells per field. (C) Cell scratch assay and (D) area of wound healing (%). (E) RNA extraction and qRT-PCR. (F) Caspase-3 activation test. (*p < 0.05, **p < 0.01, ***p < 0.001) (n = 6).

28]. Probably, n-HA particles were swallowed by the tumor cell and stimulate cells in the cytoplasm, cause MG63 cells death [45]. After endocytosis, n-HA would bind to ribosome and accumulate around the endoplasmic reticulum, resulting in arresting cell cycle and inhibiting protein synthesis in tumor cells, then n-HA could induce activated mitochondrial-dependent apoptosis in tumor cells [46]. The expression of caspase-3 gene is the most important component of apoptosis, and it is the activation of caspase-3 gene that initiates apoptosis. Caspase-3 protein function as effector to cleave various substrates including cytokeratins, the plasma membrane cytoskeletal protein alpha fodrin, the nuclear protein and others, that ultimately cause the morphological and biochemical changes seen in apoptotic cells. Caspase-3 gene can also induce cytoskeletal recombination and cell disintegration into apoptotic bodies. Therefore, n-HA leads to more apoptosis of MG63 cells through higher expression of caspase-3 gene [32]. Ki-67, a gene that may be a marker of proliferating cells, involved in chromatin compaction. Its expression is altered in many tumor types including osteosarcomas. Bcl-2 gene encodes an integral outer mitochondrial membrane protein that blocks the apoptotic death of some cells. In our experiment, n-HA could inhibit the expression of Ki-67 gene and Bcl-2 gene, results in decreased protein synthesis

of Ki-67 and Bcl-2 protein [43,44], which could promote MG63 cells apoptosis. Transwell assay and cell scratch experiment in this paper showed that CSi-Mg/n-HA scaffold could significantly delay cell invasion and migration, which may be related to the combination of low expression of Ki-67 and Bcl-2 protein and high expression of caspase-3 protein reduces the ability of cells to migration and invasion of tumor cells. In this paper, CSi-Mg/n-HA3 scaffold has a better effect on promoting tumor cell apoptosis and reducing migration than other scaffolds, which is related to the amount of n-HA on the surface of the scaffold. More n-HA on the surface of CSi-Mg/n-HA3 scaffold enhances its anti-tumor effect significantly. In this work, CCK-8 assay, apoptosis assay, viability staining, morphological staining and cell cloning experiments all proved that the scaffold could inhibit the proliferation of MG63. Through cell scratch experiment and transwell assay, it was verified that the scaffold could inhibit the migration of tumor cells.

*3.5. In vitro osteogenesis*

In order to study the osteogenic properties of scaffolds, we conducted some experiments with Rat BMSC. In cell viability staining, the scanning microscopy images in Fig. 8A indicated different cells
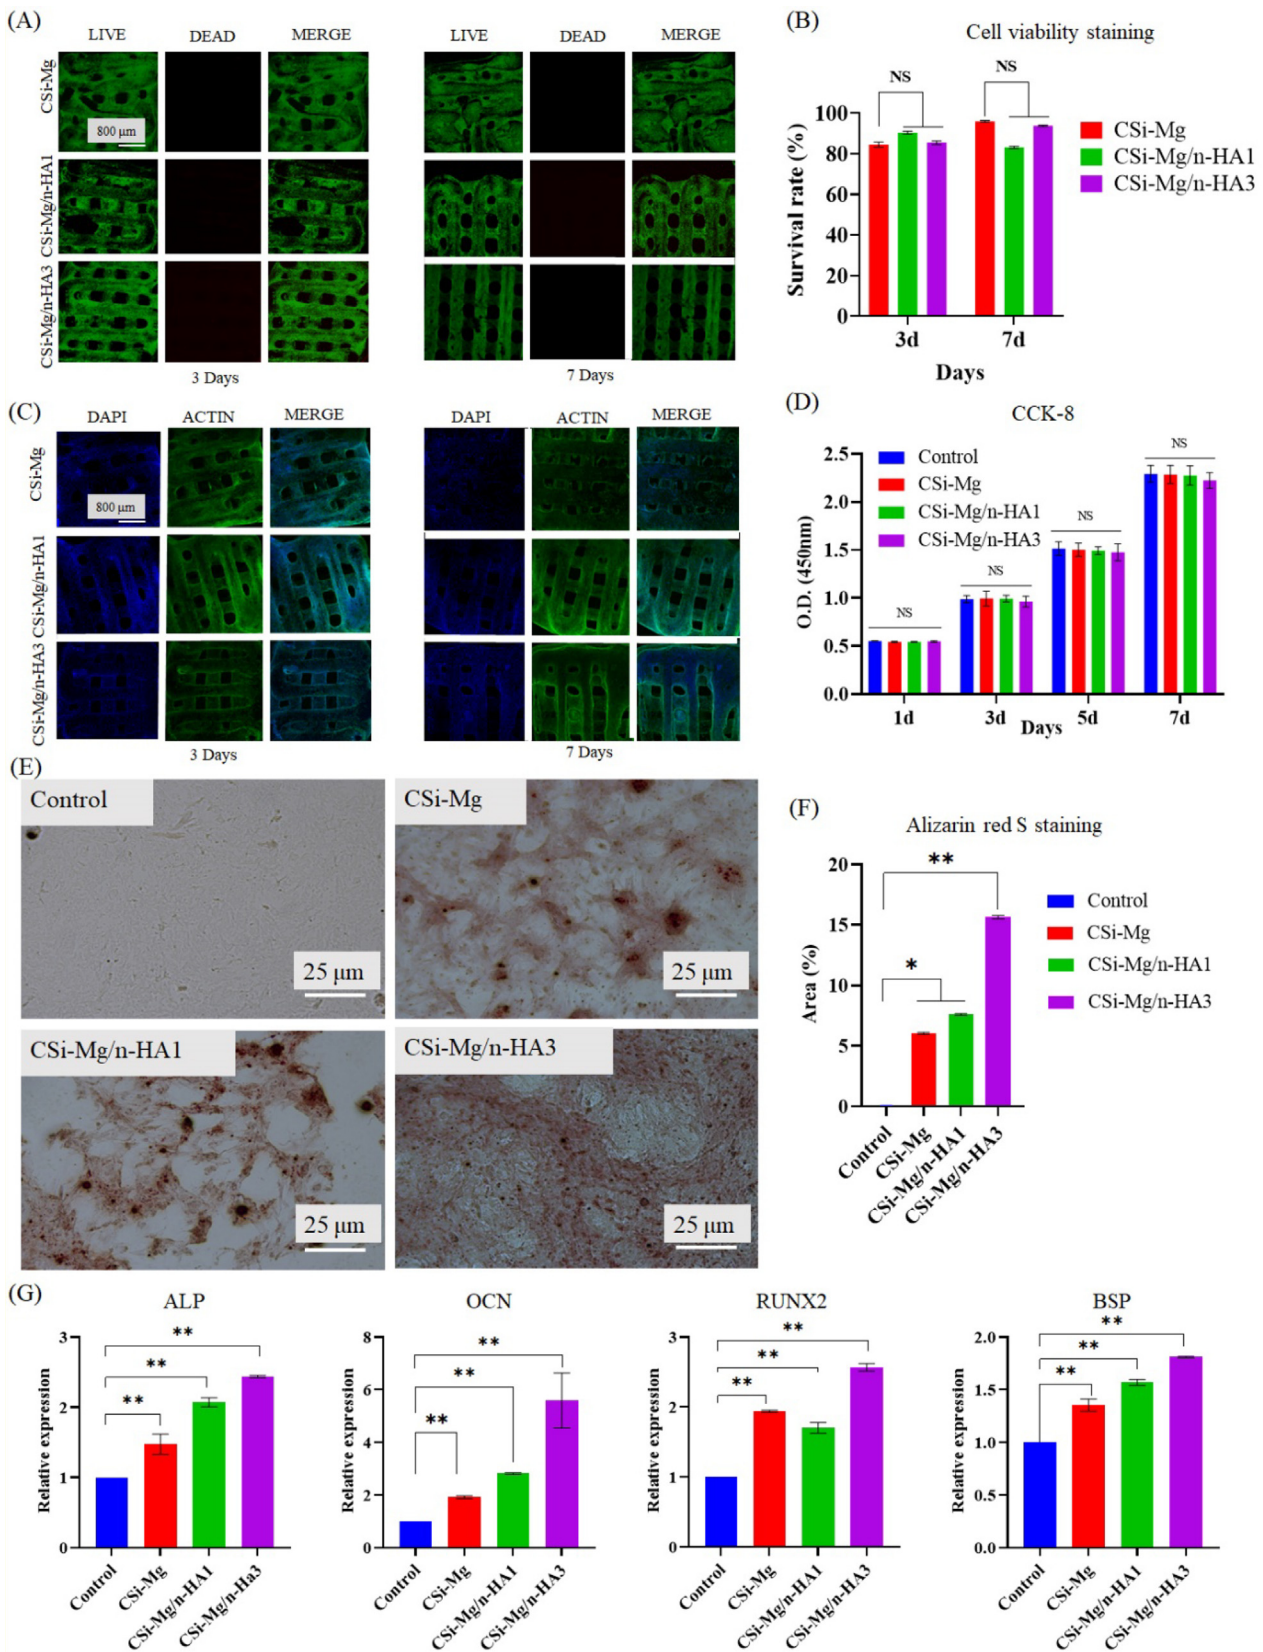

**Fig. 8.** Scaffolds can promote osteogenic of Rat BMSC in vitro. (A) Cell viability staining and (B) survival rate. (C) Cell morphology staining. (D) CCK-8 assay. (E) Alizarin red S staining and (F) dyeing area (%). (G) RNA extraction and QRT-PCR. (*p < 0.05, **p < 0.01, ***p < 0.001) (n = 6). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

(red fluorescence was used to dye the died cells, green fluorescence was used to dye live cells). We could see that each group of scaffolds had the similar fluorescence. There are no obvious dead cells in each group and survival rate showed that each group of scaffolds expressed a good survival rate on Rat BMSC (Fig. 8B) [47]. This indicated that all scaffolds have good biocompatibility. In the cell morphology staining diagram (Fig. 8C), blue fluorescence was used to dye the DAPI and green fluorescence was used to dye ACTIN. The fluorescence intensity, indicates they had no significant effect on the growth of Rat BMSC, this indicated that the cells can live on the scaffolds. On the other hand, CCK-8 experiment (Fig. 8D) showed that each group of scaffolds did not affect the proliferation of Rat BMSC. The difference was not statistically significant compared to the control group. Then, alizarin-red S assay was done to study calcium deposition. In the Alizarin-red S staining experiment (Fig. 8E) and dyeing area (Fig. 8F), it could be seen that the CSi-Mg/n-HA3 scaffolds had better osteogenic effect [48]. In RNA extraction and qRT-PCR experiments (Fig. 8G), the activities of ALP, BSP, OCN and RUNX2 were gradually improved with the increase of coating times, indicating that the more adsorption times, the better osteogenic performance [49]. This proves that CSi-Mg/n-HAx scaffolds have better osteogenic effect from the genetic level.

We use Rat BMSC to explore the effect of surface coating on the osteogenic performance of the scaffold. HA is investigated extensively due to its excellent bioactivity, biocompatibility, osteoconductivity, and chemical stability. It exhibits the same structure, function and chemical composition as bone. CSi-Mg scaffold can release of calcium, silicon and magnesium ions during the degradation process, which is good for osteogenesis. There were more calcium deposits on the surface of CSi-Mg/n-HA3 scaffold in this paper, indicating that the scaffold had good osteogenic properties [50]. In addition, we also found that CSi-Mg/n-HAx (x = 1,3) scaffolds could induce relatively high expression of ALP, OCN, BSP and RUNX2 gene. CSi-Mg/n-HA3 scaffold has a higher expression than other scaffolds, which is related to the amount of n-HA on the surface of the scaffold. More n-HA on the surface of CSi-Mg/n-HA3 scaffold enhances its osteogenic effect significantly. The n-HA particle on the surface of scaffold can enter Rat BMSC by endocytosis. By lysosomes, they are decomposed into calcium and phosphate ions [51]. Calcium ions are able to activate the sAC, cAMP, Epac, and Rap1 proteins. Followed by starting Rap1 activation, other proteins in the cell, such as Raf1 and PI3K, are activated [52]. PI3K-AKT is an essential pathway in proliferation, differentiation and cell survival, for the activation of AKT protein [53]. Upon activation of AKT, the CREB protein is phosphorylated and subsequently enters the cell nucleus and acts as a transcription factor which can provides transcription for ALP, OCN, BSP and RUNX2 genes [54]. By regulating levels of diphosphate (PPi), alkaline phosphatase (ALP) gene plays a key role in skeletal mineralization. Osteocalcin (OCN) gene expression produces OCN protein, which constitutes 1–2 % of the total bone protein. It binds strongly with apatite and calcium. Bone sialoprotein (BSP) gene expression produces BSP, BSP binds tightly to hydroxyapatite, probably BSP is important to cell-matrix interaction. Transcription factor of RUNX2 gene involved in osteoblastic differentiation and skeletal morphogenesis, it is essential for the maturation of osteoblasts and both intramembranous and endochondral ossification. ALP, OCN, BSP, and RUNX2 are some of the most important genes expressed by osteoblasts, and they collectively contribute to the formation of the osseous matrix and controlled calcification. Different bone matrix proteins have different biological functions in bone formation, scaffolds enhance the expression of these genes and thus promote osteogenic properties[55]. The expression of these genes leads the cell to differentiate osteogenesis. In general, scaffolds with n-HA adsorbed on the surface have good osteogenic properties.

## 4. Conclusions

In summary, this study developed a novel bioactive scaffold, the composite bioceramic scaffold was fabricated with interconnected porous magnesium-doped wollastonite (CSi-Mg) scaffolds as the architecture and nano-hydroxyapatite (n-HA) as the surface. Nano-hydroxyapatite coating can effectively slow down the degradation of CSi-Mg scaffolds. SBF immersion experiment in vitro showed that the composite scaffolds had good mechanical retention and the CSi-Mg/n-HA3 scaffold still had a high compressive strength (over 90 MPa) after three weeks. CSi-Mg/n-HA3 scaffold induced about 50 % of cell death for human osteosarcoma cells (MG-63) in vitro, indicating that the composite scaffolds had good anti-tumor effect. In addition, we used Rat BMSC to study the effect of the scaffolds on the osteogenic properties, and the results showed that the scaffolds with surface modification have a good effect on the osteogenic properties of the scaffold. We believe this approach presents a promising strategy for developing high strength and anti-tumor bioceramic scaffolds, indicating a promising clinical tool for the treatment of tissue damage after resection of osteosarcoma.
